#### Abstract

In this research study, molecular diameter for various pure compounds were estimated using seven methods, in which three diameters are based on scaled particle theory (SPT) and the others are obtained from actual molecular volumes assuming hard sphere shape for molecules by using Bondi, Edward and Van der Veen methods. The seventh one was obtained from a relationship between molecular volume and parachor. Correlation among seven types of molecular sizes for pure components is reported. Calculated diameters were used to prediction surface tension of 108 pure compounds based on SPT. The results demonstrated that the hard sphere diameter which was obtained from reported correlations can be used to estimate the pure substances surface tension with good accuracy. The absolute average deviation percent for surface tension prediction of pure fluids with different correlations is $1.3 \%$, $11.26 \%, 11.52 \%, 32.42 \%, 14.62 \% 12.16 \%$ and $1.95 \%$.

[^0]
## Introduction

Studying the thermodynamic and transport properties of liquids and liquid mixtures is useful for many purposes, one of which is to obtain information on the molecular interactions among the components of the mixtures [1-2]. The thermodynamic and transport properties of liquids and liquid mixtures1 have been used to understand the molecular interactions between the components of the mixture and also for engineering applications concerning heat transfer, mass transfer, and fluid flow [3]. As a fundamental parameter, surface tension is the single most accessible parameter that describes the thermodynamic state and contains implicit information on the internal structure of a liquid interface [4]. Apart from this theoretical interest, a detailed understanding of the behaviour of a vapor-liquid interface, such as enrichment of one component in a liquid surface, is important for modelling a distillation process [5]. Surface tension is important in many scientific areas, including heat transfer, mass transfer, gas absorption, distillation, liquid extraction, condensation, fluid flow, material sciences, environmental sciences, process simulation, and molecular dynamics [6-11], playing a significant role in several industries such as foods, paints, detergents, pharmaceuticals, agro-chemicals and petroleum engineering [12-17]. In addition, the surface tension of liquids must often be considered in designing rational chemical process equipment involving interphase heat and mass transfer [18-19].
Several methods have been developed to estimate the surface tension of pure fluids including parachor method [20], corresponding states model [21-22], the gradient theory [23], the perturbation theory [24]; the density functional theory [25] and group contribution method [26]. In this work, scaled particle theory (SPT) was employed to estimate the surface tension of polar and non-polar pure fluids. For
estimating surface tension of pure fluids from SPT, knowing hard sphere diameter is necessary. We represent seven methods for calculating hard sphere diameter and report correlation among them. Based on calculated hard sphere diameter, surface tension of 108 pure substances is predicted with SPT. The first work on scaled particle theory (SPT) was published at 1959. In that study several exact conditions were derived and the dependence of surface tension on curvature was also given. It was reported that the macroscopic consideration on surface tension can sometimes be successfully extrapolated to molecular dimensions [27]. Additional papers applied SPT to one and two-dimensional systems [28]. SPT has been applied with considerable success to various studies, i.e., surface tension of pure fluids [29-30], partition coefficient in phase Equilibria [31], volatility in extractive distillation [32], solubility of gases in liquids [33-34], micellization of surfactants [35-37], glass transition of liquids [38], and estimation of thermodynamic properties [39-40]. The success of the theory encouraged workers to extend the formalism to real fluids [41], surface tension prediction for mixtures [42], critical temperature prediction [43] and determine the Lennard-Jones energy parameter [44].
SPT was extended and an approximate for the work of creating a spherical cavity in a real fluid was determined. This expression was used to derive an equation for evaluation of surface tension of pure substances [45]. The calculated surface tension by SPT is very sensitive to hard sphere diameter and a small change in hard sphere diameter cause a significant change in calculated surface tension. Therefore, for calculating surface tension with acceptable results it is necessary to have hard sphere diameter with high accuracy.

## Theory

Following equation was derived for calculating surface tension of pure substance based on SPT [45]:

$$
\begin{equation*}
\sigma=\frac{k T}{4 \pi a^{2}}\left\{\frac{12 y}{1+y}+18\left(\frac{y}{1+y}\right)^{2}\right\}-\frac{p a}{2} \tag{1}
\end{equation*}
$$

where $\sigma$ is the surface tension of pure substance, $k$ is the Boltzmann's constant and $p, T$ are the pressure and temperature, respectively. $a$ is the hard sphere diameter and $y$ is the packing fraction given by $y=\pi \rho a^{3} / 6$ and $\rho$ is the number density.
For calculating surface tension of pure substances, it is necessary to have hard sphere diameter. Molecular diameter can be estimated by seven methods:

The first type of molecular diameter ( $a_{\mathrm{w}}$ ) can be determined from the Van der Waals molecular volume ( $V_{\mathrm{W}}$ ). $V_{\mathrm{W}}$ is regarded as the summation of individual volume of molecular fragments [46]:

$$
\begin{equation*}
\pi a_{\mathrm{w}}^{3} / 6=V_{\mathrm{W}} \tag{2}
\end{equation*}
$$

The second type of molecular diameter $\left(a_{\beta}\right)$ is obtained from experimental value of isothermal compressibility ( $\beta$ ) using following equation derived from SPT [47]:
$\beta=\left(\frac{\pi a_{\beta}^{3}}{6 k T}\right)\left[\frac{\left(1-y_{\beta}\right)^{4}}{y_{\beta}\left(1+2 y_{\beta}\right)^{2}}\right]$
Where $y_{\beta}=\pi \rho a_{\beta}^{3} / 6$.
The third type of molecular diameter $\left(a_{\mathrm{E}}\right)$ is determined from the actual molecular volume ( $V_{\mathrm{E}}$ ) that can be calculated by the method of Edwared in which $V_{\mathrm{E}}$ is equal the summation of individual volume of molecular fragments [48]:
$\pi a_{\mathrm{E}}^{3} / 6=V_{\mathrm{E}}$
The fourth type of molecular diameter $\left(a_{\mathrm{V}}\right)$ is determined from the correlation of $V_{\mathrm{w}}$ with the
hard sphere diameter [49]. The proposed correlation is:
$\left(\frac{\pi}{6}\right) N a_{\mathrm{V}}^{3}=-10+1.13 V_{\mathrm{W}}$
With $a_{\mathrm{V}}$ (in cm ) and $V_{\mathrm{W}}$ (in $\mathrm{cm}^{3} / \mathrm{mol}$ ) and $N$ is Avogadro's number.
The fifth type of molecular diameter $\left(a_{P}\right)$ is calculated from parachor data. Sugden defined parachor with the following equation [50]:
$P=\sigma^{1 / 4} M /\left(\rho_{1}-\rho_{\mathrm{v}}\right)$
$P$ is the parachor, $M$ the molecular weight of the compound, and $\rho_{1}$ and $\rho_{\mathrm{v}}$ are the densities of the liquid and vapour in equilibrium. It was found that $P$ could be simply calculated from group additivity contributions. Although the dependence of surface tension on density predicted by Eq. (6) has been theoretically derived close to the critical point [51] the parachor has continued to be mainly regarded as an empirical quantity, with the large amount of data available clearly indicating a relationship with the molecular volume. Telang related the parachor to molecular dimensions by the following expression [52]:
$a_{\mathrm{P}}=0.92 \times 10^{-8} P^{0.4} / T_{\mathrm{c}}^{0.1}$
Where $a_{\mathrm{P}}$ is the molecular diameter in $\mathrm{cm}, T_{c}$ is the critical temperature expressed in K. Eq. (7) has a reliability of $\pm 2.2 \%$ for all compounds except those having $-\mathrm{OH},-\mathrm{C} \equiv \mathrm{N},-\mathrm{COOH}$, or $>\mathrm{C}=0$ groups and one to three non-functional carbon atoms. For these latter the constant 0.92 becomes 0.96 [53].
The parachor of pure compounds was analysed from the point of view of SPT [54]. They used theories of liquids and derived a simple relationship between the molecular parachor and the hard sphere diameter:
$P=2.841 \times 10^{19} T^{1 / 4} f(y) a_{\mathrm{S}}^{2.5}$
Where $a_{\mathrm{S}}$ is the molecular diameter. $f(y)$ is defined with following equation:
$f(y)=\left[\frac{y(2+y)^{1 / 4}}{y(1-y)^{1 / 2}}\right]$
The sixth type of molecular diameter ( $a_{\mathrm{S}}$ ) can be calculated with Eqs. (8), (9) using literature data of parachor [53].

The seventh type of molecular diameter $\left(a_{\sigma}\right)$ can be calculated with Eq. (1) using surface tension literature data for pure compounds [5557].

## Result and Discussion

We used equations (1), (2), (3), (4), (5), (7), (8) and (9) for calculating molecular diameters ( $a_{\mathrm{W}}, a_{\beta}, a_{\mathrm{E}}, a_{\mathrm{V}}, a_{\mathrm{P}}, a_{\mathrm{S}}$ and $a_{\sigma}$ ) of various pure compounds. The parameters required for the calculation together with experimental surface tension are collected in Table 1 where the compounds are ordered according their type. The results of calculation are summarised in Table 2. First, correlation between $a_{\beta}, a_{\mathrm{E}}$ was investigated as illustrated in Figure 1, where the values of $a_{\beta}$ inside the bracket in Table 2 were used for the plot (For these compounds, experimental isothermal compressibility was available). As it is obvious from Figure 1, there is
one can estimate $a_{\beta}$ values from $a_{\mathrm{E}}$ using following equation due to the lack of experimental isothermal compressibility factor:
$a_{\beta}=1.146 a_{\mathrm{E}}-1.1591$
Here, part of the $a_{\beta}$ values was obtained from $a_{\mathrm{E}}$ using Eq. (10), since the experimentally available $a_{\beta}$ data are not so numerous.
At the next step correlation among $a_{\mathrm{w}}, a_{\beta}, a_{\mathrm{E}}, a_{\mathrm{V}}, a_{\mathrm{P}}, a_{\mathrm{S}}$, and $a_{\sigma}$ was investigated as illustrated in Figures 2, 3, 4, 5, 6 and 7 , where the values of $a_{\beta}$ inside the bracket in Table 2 were used for the plot. Regression line is given by Eqs. (11), (12), (13), (14), (15) and (16):
$a_{\sigma}=1.1329 a_{\mathrm{E}}-1.1670$
$a_{\sigma}=0.9929 a_{\beta}-0.0337$
$a_{\sigma}=0.9923 a_{\mathrm{V}}-0.0329$
$a_{\sigma}=1.1148 a_{\mathrm{w}}-1.0481$
$a_{\sigma}=1.3789 a_{\mathrm{P}}-0.8133$
$a_{\sigma}=1.0108 a_{\mathrm{S}}-0.0709$ good linearity between $a_{\beta}$ and $a_{E}$. It means that

The calculated diameters via Equation (1), (2), (3), (4), (5), (7), (8) and (9) was used to predict surface tension of pure substances at 25 ${ }^{\circ} \mathrm{C}$. The overall absolute average deviation percent (AAD\%) is demonstrated in Table 2 as AAD1\%. As seen in Table 2, the difference between diameters which were calculated from all methods is not significant but the difference
between overall AAD percent is very large. On the other hand, small variations in the value of the hard sphere diameter cause the most significant changes to the surface tension. The reason for this matter is that the hard sphere is raised to a $3^{\text {rd }}$ power in the packing fraction. This magnifies differences very significantly. Therefore, for prediction surface tension of pure
substances accurately, it is very important to have a good approximation of hard sphere diameter. The overall AAD\% from Table 2 shows that the hard sphere diameter which is calculated from Eqs. (8) and (9) can be used in Equation (1)
for estimation of pure substances with good accuracy. Calculated surface tension for pure compounds compared with experimental data in Figure 8.

Figure 8. Calculated surface tension based on $a_{\mathrm{S}}$ versus experimental surface tension for pure compounds at $25^{\circ} \mathrm{C}$. The line corresponds to $\sigma_{\text {Calc. }}=\sigma_{\text {Exp. }}$.

Equations (11) - (16) were used to calculate the hard sphere diameter. Surface tension of pure substances was calculated with new hard sphere diameters. The overall AAD\% for new case is reported in Table 2 as AAD2\%. Average of AAD1\% for the seven methods in Table 2 is $37.8 \%$ while average of AAD2\% for the seven methods is $12.17 \%$. This confirms that calculation of surface tension with diameters obtained from Equations (11) - (16) decreases the overall $\mathrm{AAD} \%$.

## Conclusion

In this work, seven methods were presented for calculating the hard sphere diameter of pure substances. These models were applied for 108 pure substances and hard sphere diameter of studied substances calculated. Based on the
calculated hard sphere diameters, the correlation among them reported. Surface tension of all studied pure substances was predicted with Scaled Particle Theory (SPT) by using calculated hard sphere diameters $\left(a_{\mathrm{w}}, a_{\beta}, a_{\mathrm{E}}, a_{\mathrm{V}}, a_{\mathrm{P}}, a_{\mathrm{S}}\right.$, and $a_{\sigma}$ ) and hard sphere diameters obtained from correlations (Eqs. 10-16). AAD1\% shows the overall absolute average deviation percent for surface tension calculation by using calculated hard sphere diameters $\left(a_{\mathrm{W}}, a_{\beta}, a_{\mathrm{E}}, a_{\mathrm{V}}, a_{\mathrm{P}}, a_{\mathrm{S}} \quad\right.$ and $\left.a_{\sigma}\right)$ and $\mathrm{AAD} 2 \%$ showed the overall average absolute deviation for surface tension calculation by using predicted hard sphere diameters (Eqs. 10-16). Overall $\mathrm{AAD} 1 \%$ shows that using $a_{\mathrm{S}}$ and $a_{\sigma}$ produce more accurate results in compare with other
methods for surface tension. For calculating $a_{\sigma}$, surface tension value is required therefore the hard sphere diameter which is calculated from parachors can be used in Eq. (1) for estimation of surface tension of pure substances with good accuracy. Although calculation of surface tension with hard sphere diameters estimated from correlations (obtained in this work), decreases the AAD\% significantly. Average of AAD1\% for the seven methods is $37.8 \%$ while average of AAD2\% for the seven methods is $12.17 \%$.
